A liquid-helium temperature study of Fe$^{2+}$ and Mn$^{2+}$ ions has been carried out on a single crystal of Fe$^{2+}$-doped ZnSiF$_6$·6H$_2$O at 5–35 K at 170, 222.4 and 333.2 GHz. The spectra are found to be an overlap of two magnetically inequivalent Fe$^{2+}$ ions, as well as that of an Mn$^{2+}$ ion. From the simulation of the EPR line positions for the Fe$^{2+}$ ($S = 2$) ions the spin-Hamiltonian parameters were estimated for the two inequivalent Fe$^{2+}$ ions at the various temperatures. From the relative intensities of lines the absolute sign of the fine-structure parameters have been estimated. In addition, the fine-structure and hyperfine-structure spin-Hamiltonian parameters for the Mn$^{2+}$ ion, present as impurity at interstitial sites, were estimated from the hyperfine allowed and forbidden line positions. The particular virtues of such a single-crystal study vs. that on powders are noted.

1. Introduction

The non-Kramers Fe$^{2+}$ ion was previously considered EPR silent, because it typically possesses a very large zero-field splitting, so that the quantum of energy at X-band (~9.5 GHz) is not sufficient to match the energy-level separation for the allowed transitions $\Delta M = \pm 1$, where $M$ is the electronic spin magnetic quantum number. In addition, its spin–lattice relaxation times are rather short at higher temperatures, so that the EPR lines are sufficiently broadened out, that they are not observed near room temperature. However, one can observe EPR transitions for the Fe$^{2+}$ ion at low temperatures and at sufficiently high frequencies, such that the microwave energy is sufficient to match the required energy-level separations. Recently, such studies, all on powder samples, have been reported: (i) Fe$^{2+}$ in the reduced rubredoxin model [Fe(SPh)$_4$]$^{2-}$ by Knapp et al. [1], (ii) Fe$^{2+}$ in hexaaqua complexes by Telser et al. [2], (iii) Fe$^{2+}$ in bis(2,2′-bi-2-thiazoline)bis(isothiocyanato)iron(II) by Ozarowski et al. [3], (iv) Fe$^{2+}$ in Fe(SO$_4$)$_2$·4H$_2$O by Krzystek et al. [4,5], (v) Fe$^{2+}$ in [Fe$_2$(OH)$_2$(tmtacn)$_2$]$_2$ by Knapp et al. [6], and (vi) Fe$^{2+}$ in CsFe(D$_2$O)$_6$PO$_4$ by Carver et al. [7]. All these studies on biological samples containing undiluted Fe$^{2+}$ ions were on amorphous powders or frozen solutions, and the values of the zero-field splitting (ZFS) parameter, $D$, was quite large, ranging from 11,561 to 172,452 Gauss. It is the purpose of this paper to report on a detailed multifrequency EPR study of an Fe$^{2+}$-doped single-crystal at very high frequencies (170, 222.4 and 331.2 GHz) yielding the temperature variation of the Fe$^{2+}$ spectra from 5 to 35 K, and to estimate its spin-Hamiltonian parameters over this temperature range. The absolute sign of the zero-field splitting (ZFS) parameter, $D$, was estimated from the relative intensities of the lines at liquid-helium temperature. Mn$^{2+}$ is present as an impurity in the chemicals used for growing the crystals. Its EPR spectra were also analyzed, and its spin-Hamiltonian parameters estimated.

2. Experimental arrangement

2.1. Spectrometers

2.1.1. 170 GHz

EPR measurements at 170 GHz were carried out at 5–35 K at ACERT (Advanced Center for Electron Spin Resonance Technologies) at Cornell University on a home-built spectrometer, based on the principles of quasi-optics, operating in the induction-mode [8]. It is equipped with a Fabry-Pérot resonator, with a separation of 1–2 cm between the mirrors, which allows one to place large single crystals in it. A superconducting magnet was employed. The field was calibrated using a Mn$^{2+}$ marker, $g = 2.0145$, with a precision of 5–10 G. Magnetic field modulation at 82 kHz and 3–10 mT amplitude was employed. Under these standard operating conditions, the spectra obtained appear to be absorption curves, as though there were no modulation, instead of the usual first derivative ones. This is due to rapid passage effects as originally de-
scribed by Portis [9]. Because of the low temperatures, the relaxation times are long and the conditions of rapid passage are fulfilled, (i.e., relaxation times are larger, than the period of modulation and the microwave field is larger than 1/(γT1) and 1/(γT2) [10]. Then the line is distorted into the shape of an absorption line (Ref. [10]). Whereas the line shapes obtained in the rapid passage spectra are significantly modified, the line positions remain unchanged, as discussed by Chemerisov et al. [11]. (Note that the use of the Fabry–Perot resonator with its substantial quality factor improves S/N, but it also enhances, B1 at the sample. In addition, it is sensitive to microphonics, preventing the use of modulation frequencies lower than ca. 80 kHz. These normal operating conditions undoubtedly enhanced the rapid passage effects.)

2.1.2. 222.4 and 331.2 GHz

High-frequency EPR spectra at 222.4 and 331.2 GHz were recorded on a home-built spectrometer at the EMR facility of NHMFL (National High Magnetic Field, Tallahassee, Florida). The instrument was a transmission-type device in which microwaves are propagated in cylindrical lightpipes. The microwaves were generated by a phase-locked Virginia Diodes source generating a frequency of 13 ± 1 GHz and producing harmonics of which the 4th, 8th, 16th, 24th and 32nd were available. A superconducting magnet (Oxford Instruments) capable of reaching a field of 17 T was employed. The field was calibrated using DPPH, g = 2.0037. The differences between ‘calibrated’ and ‘uncalibrated’ fields are 50–90 Gauss. No resonance cavity was used. Detection was provided by a liquid-helium-cooled InSb hot-electron bolometer (QMC Ltd., Cardiff, UK). Magnetic field modulation at 40 kHz and ca. 2 mT amplitude was employed. A Stanford SR830 lock-in-amplifier was used to convert the modulated signal to a DC voltage.

2.2. Crystal: sample preparation and structure

ZnSiF$_6$·6H$_2$O crystals were grown by dissolving metallic zinc in fluorsilicic acid and slowly evaporating the filtered solution at room temperature, to which was added FeSO$_4$ solution in distilled water so that there was one Fe$^{2+}$ ion for every 500 Zn$^{2+}$ ions. A drop of very dilute fluorsilicic acid was added to the solution to prevent hydrolysis. Crystals were selected from crops recrystallized from aqueous solution by slow evaporation. Nice single colorless prismatic crystals with hexagonal cross section were obtained within a few days. The clear color indicated that Fe$^{3+}$ ions were not present, as they would otherwise impart a yellowish hue to the crystals. Elemental analysis confirmed that indeed Fe$^{2+}$ ions were present in the sample. The crystals were stored in mineral oil to avoid deliquescence. The sample was covered with a layer of Apiezon grease to prevent oxidation and deliquescence inside the resonators.

The room temperature crystal structure of ZnSiF$_6$·6H$_2$O was determined by Ray et al. [12]. Accordingly, the crystals are characterized by the unit cell parameters: $a = 9.363$ (3), $c = 9.690$ (5) Å, $Z = 3$, with the space group $R3$. However, based on our EPR results described below a structural phase transition may occur at very low temperatures, so it is not clear whether this structure accurately describes the EPR spectra.

2.3. EPR spectra

No spectrum could be observed from room temperature (RT) down to ca. 40 K. [This confirms that Fe$^{3+}$ ions are not present in the sample, since they do exhibit EPR lines at RT (295 K).] Thus, the spectra were recorded only below 40 K, specifically at 35, 20, 17, 10 and 5 K. The temperature variation of the EPR spectrum indicated that the site symmetry changed over the range of 35–20 K, below which it remained unchanged. All these single-crystal spectra also display a central Mn$^{2+}$ sextet in addition to the Fe$^{2+}$ lines. Although the Mn$^{2+}$ ion does normally exhibit an EPR spectrum at RT, no Mn$^{2+}$ spectrum was seen at RT in the present case. This could be due to a Mn$^{2+}$–Fe$^{2+}$ interaction which would shorten the Mn$^{2+}$ relaxation times, thereby broadening the Mn$^{2+}$ EPR lines at higher temperatures.

Figs. 1 and 2, respectively, show the 5 K EPR absorption-like spectra at 170 GHz and the first-derivative EPR spectra at 222.4 GHz for the orientations with the external magnetic field (B) parallel and perpendicular to the c-axis, the latter being in the direction perpendicular to one of the sides of the hexagonal cross section of the single crystal. For each of these orientations of B, there are found two sets of spectra due to two magnetically inequivalent Fe$^{2+}$ ions, hereafter referred to as Fe$^{2+}$ ions at site a and b. Fig. 3 shows the 10 K first-derivative EPR spectrum at 222.4 and 331.2 GHz for the magnetic field orientation parallel to the c-axis of the single crystal. At 17 K and 170 GHz the absorption-like spectrum observed is shown in Fig. 4 just for B oriented perpendicular to the c-axis of the single crystal. Also, at this temperature, the last line of site b could not be observed within the magnetic field range 5.2–6.6 T used for recording the spectrum. At 20 K, we just obtained the first-derivative spectrum at 222.4 GHz for B in the parallel orientation to the c-axis of the single

![Fig. 1. 170-GHz EPR absorption-like lines at 5.5 K for the orientation of B parallel and perpendicular to the crystal c-axis. The EPR lines belonging to the Fe$^{2+}$ ions at the two sites are indicated as $a_1$, $a_2$, $a_3$, $a_4$, and $b_1$, $b_2$, $b_3$ in increasing value of the magnetic field. The indicated field values are as scaled from the plot; the precision is 5–10 G, as described in Section 2.1.](image-url)
crystal, as shown in Fig. 5. At 35 K the absorption-like spectrum observed at 170 GHz for the orientation of B parallel and perpendicular to the crystal c-axis. The EPR lines belonging to the Fe$^{2+}$ ions at the two sites are indicated as $a_1$, $a_2$, $a_3$, $a_4$ and $b_1$, $b_2$, $b_3$, $b_4$ in increasing value of the magnetic field. The inset in the figure for the perpendicular orientation of B shows an amplified view of the Mn$^{2+}$ central hyperfine sextet, as well as the Fe$^{2+}$ $a_2$, $a_3$, $a_4$ lines. The indicated field values are as scaled from the plot; the precision is 50–100 G, as described in Section 2.1. The low-frequency background is due to instrumental artefact.

3. Analysis of Fe$^{2+}$ EPR spectra

3.1. Spin Hamiltonian (SH)

The EPR spectral line positions observed at the various temperatures and for different orientations of B were fitted simultaneously to estimate the SH parameters for the Fe$^{2+}$ ($S = 2$ spin state) characterized by orthorhombic symmetry, including the second and fourth order zero-field splitting (ZFS) terms [13,14]

$$H = \mu_B [g_1 B_S S_z + g_2 (B_x S_x + B_y S_y)] + D(S_z^2 - S(S + 1)/3)$$
$$+ E(S_x^2 - S_y^2) + B_0^2 O_0^2 + B_2^2 O_2^2 + B_4^2 O_4^2,$$  \hspace{1cm} (1)

where $\mu_B$ is the Bohr magneton; the magnetic z-axis is along the respective symmetry axes, which are parallel and perpendicular to the c-axis of the crystal for sites a and b, respectively, and the $O_i^2$ are spin operators [13,14]. Inclusion of a small second-order term depending on E and the fourth-order term $B_4^2 O_4^2$ improved the quality of the fits significantly. The very small values of E (Table 1) indicate that the Fe$^{2+}$ ions see a predominantly axial field with a very small (trigonal) distortion in the ZnSiF$_6$·6H$_2$O crystal. The last two terms in Eq. (1) were found to have negligible effects on the fitting. Thus, within experimental error, the values of the non-axial parameters $B_2^4$ and $B_4^2$ can be assumed to be zero.

3.2. Zero-field energy levels

The zero-field energy levels are shown in Fig. 7 for positive D [6]. In the absence of any ZFS (Fig. 7 left), the $S = 2$ spin system of the Fe$^{2+}$...
ion possesses five degenerate energy levels ($M = \pm 2, \pm 1, 0$). These are split by the ZFS terms, i.e., the second and subsequent terms in Eq. (1), thereby lifting the degeneracy. The splitting in the middle of Fig. 7 is caused by an axial field ($D = 0, E = 0$), whereas the splitting shown in the right part of this figure is caused by a rhombic distortion ($D \neq 0, E \neq 0$). The five zero-field eigenfunctions depending on $D$ and $E$ are expressed as follows:

$$|2^e\rangle = \frac{1}{\sqrt{2}} \left( 1 + \frac{D}{\sqrt{D^2 + 3E^2}} \right) |+2\rangle + \frac{1}{\sqrt{2}} \left( 1 - \frac{D}{\sqrt{D^2 + 3E^2}} \right) |-2\rangle;$$

$$|1^e\rangle = \frac{1}{\sqrt{2}} (|+1\rangle + |+1\rangle);$$

$$|1^o\rangle = \frac{1}{\sqrt{2}} (|+1\rangle - |+1\rangle);$$

$$|0\rangle = \frac{1}{\sqrt{2}} (|+1\rangle + |+1\rangle);$$

At very high magnetic fields the energies of these levels will increase linearly with the magnetic field ($B$) intensity for the orientation of $B$ parallel to the magnetic $z$-axis of the crystal, when the Zeeman term is taken into account.

3.3. Relative intensities of EPR lines and the absolute sign of the ZFS parameter $D$

For the orientation of $B$ parallel to the $c$-axis, which is parallel to the magnetic $z$- and $x$-axes of the Fe$^{2+}$ ions at sites $a$ and $b$, respectively, the intensities of the higher field lines $a_4$ and $b_4$ are smaller and larger relative to the lower field lines $a_1$ and $b_1$, respectively. This indicates the absolute sign of $D$ to be negative for both the sites $a$ and $b$, according to the discussion given by Abragam and Bleaney [13] and Misra [14], taking into account the transformation of the ZFS parameter $D$ from the magnetic $x$- to the $z$-axis for site $b$. The sign of the other SH parameters relative to $D$ as found from the fitting are correct. The signs of the SH parameters in Table 1 are listed in accordance with this.

3.4. Evaluation of Fe$^{2+}$ SH parameters from EPR line positions

The spin-Hamiltonian parameters which simultaneously best reproduce the line positions for all the frequencies of measurement at each temperature were determined with a simulation algorithm,
The magnetic z-axes for the two sites were found to be oriented along the directions parallel and perpendicular to the c-axis. This perpendicular direction is also perpendicular to an edge of the hexagonal cross section as shown in Fig. 8, which depicts the two sets of magnetic axes in relation to crystal morphology of hexagonal prismatic crystals. From the observed equal intensities of the EPR lines for the Fe\(^{2+}\) ions at sites a and b, it was concluded that in the six equivalent sites of b corresponding to the six edges of the hexagonal cross section of the crystal, and perpendicular to the c-axis of the crystal which corresponds site a, the Fe\(^{2+}\) ions are statistically distributed equally, and in a manner such that the intensities of the EPR lines are about the same for the two sites a and b. Since at temperatures higher than 5 K, the spectra were recorded for only one orientation of B, either parallel or perpendicular to the c-axis, only the values of \(g_b\) (site a), \(g_s\) (site b) or \(g_0\) (site b), \(g_{s}(\text{site } a)\) could be determined from the spectral line positions in those cases. At 5 K in the perpendicular orientation for B, the spectrum for 222.4 GHz shown in Fig. 2 displays a rather intense Mn\(^{2+}\) central sextet. A closer look at this sextet, as shown in the inset of Fig. 2 reveals that there are two Fe\(^{2+}\) lines which overlap these Mn\(^{2+}\) lines.

Examing the values of the SH parameters at all temperatures as listed in Table 1, it is seen that E, the parameter that indicates rhombic distortion of the axial field is relatively very small as already noted. Specifically \(|E| < 10\) G for site a and \(|E| < 25\) G for site b, which amounts to \(|E/D| \approx 0.02\) for site a and \(|E/D| \approx 0.01\) for site b. This implies that any departure from axial symmetry is extremely small. It is further noted, that the values of \(g_{0}\) and \(D\), and \(E\) in Table 1 for 35 K are substantially different from those at 5–20 K. This indicates that the crystal undergoes some kind of a phase transition between 35 and 20 K. At 35 K, it would appear that sites a and b become almost equivalent, as the values of \(E\) and \(D\) for the two sites are about the same.

### 4. Analysis of Mn\(^{2+}\) EPR spectra

The Mn\(^{2+}\) EPR spectrum is always present in the low temperature spectra studied. It is first noted that the Mn\(^{2+}\) central sextet becomes very sharp at high magnetic fields, because of suppression of second-order perturbation terms due to the Zeeman term becoming rather dominant. They are weakly split due to interac-
tion with the Fe²⁺ ions in the vicinity. Of these, the 222.4 GHz EPR spectrum, in Fig. 9, shows all the pertinent features clearly. In this spectrum, a central Mn²⁺ sextet appears at about 7.9 T, similar to that in a polycrystalline host [16,17]; reflecting the manner in which the Mn²⁺ ions enter interstitially in the ZnSiF₆·C₆H₂O single crystal. In addition, a non-central Mn²⁺ hyperfine sextet is observed at about 2.76 T. (In fact, there are eight lines seen here; there appears to be an overlap due to another Mn²⁺ species, characterized by almost the same parameters.) The polycrystalline Mn²⁺ spectrum is well understood; the estimation of the zero-field splitting parameters from the hyperfine doublet separations is described in detail by Misra [16,17]. The spin Hamiltonian for the Mn²⁺ ion (electron spin \( S = \frac{5}{2} \), nuclear spin \( I = \frac{5}{2} \)) in an orthorhombic site symmetry is given by [17].

The allowed hyperfine lines are indicated as 1, 2, 3, 4, 5, 6. The indicated field values are 22.2 GHz (5 K). The insets show amplified views of the Mn$^{2+}$ hyperfine sextets. The splitting of the forbidden hyperfine lines ($H_{\text{electron-Zeeman}}$, nuclear-Zeeman and the electron-nuclear hyperfine interactions, respectively. In this equation the first three terms represent the ZFS (zero-field splitting) term, which can be written for non-axial (orthorhombic) symmetry as:

$$H_{\text{ZFS}} = D\left(S_x^2 - \frac{1}{3}S(S + 1)\right) + \frac{1}{2}E(S_x^2 + S_z^2).$$

(4)

Here, $z$ denotes the principal axis of the second-order ZFS tensor; $D$ and $E$ are the axial and orthorhombic ZFS parameters, and $S_x, S_y, S_z \pm iS_z$. In [17], a formula is provided, which allows one to estimate the value of the ZFS parameter $D$ for the Mn$^{2+}$ ion from the splitting of the forbidden hyperfine lines $\Delta \nu = \pm 1$, where $m$ is the nuclear magnetic quantum number) of the Mn$^{2+}$ central sextet shown in Fig. 10:

$$D^{(\pm)} = \pm \frac{5|A_1|}{18} \left[ \frac{18G_0}{F(\eta)/|A_1|} \right] \left( 17 + 2 \frac{|\Delta B_{ex}/C_0^2|}{B_0|A_1^2|} \right).$$

(5)

where $|\Delta B_{ex}|$ is the experimentally observed separation between the two peaks corresponding to the two hyperfine forbidden transitions, $B_0$ is the center of the hyperfine sextet, $G_0 = h \nu$, $\nu$ is the resonance frequency, and $A$ is the hyperfine-interaction constant, $\eta = \frac{\mu}{\mu_0}$ and

$$F(\eta) = \left\{ \left( \frac{2 + 3\eta^2}{2 + \eta^2} \right)^2 + \eta^2 \left( \frac{25}{18} \frac{10(2 - \eta^2)}{3(2 + \eta^2)} + 4 \left( \frac{2 - \eta^2}{2 + \eta^2} \right)^2 \right) \right\}.$$  

(6)

Each of the six $(2I + 1 = 6)$ intense lines in the hyperfine sextet in Fig. 10 is an allowed hyperfine line ($\Delta \nu = 0$), indicated as 1, 2, 3, 4, 5, 6. To the right (i.e. higher magnetic field) of each allowed hyperfine line and in between adjacent allowed hyperfine lines, the five sets of hyperfine forbidden doublets, indicated as CAL below the plot of the spectrum. The indicated field values are as scaled from the plot; the precision is 50–100 G, as described in Section 2.1.

### 4.1. Calculation of the value of the ZFS parameter $D$ for the Mn$^{2+}$ ion

The values of $B_0$, the center of the hyperfine sextet, $|\Delta B_{ex}|$, the average distance between adjacent hyperfine lines, as well as the average separation between two adjacent forbidden hyperfine lines $|\Delta B_{ex}^{(\pm)}|$, as shown in Fig. 10 are estimated as follows:

- $B_0 = 78.878$ G; $|\Delta B_{ex}^{(\pm)}| = 22.8$ G; $|\Delta B_{ex}^{(\pm)}| = 96$ G. Using $\mu_B = \mu_0 h / 2G_0$ for the Mn$^{2+}$ ion is: $\mu_B = \mu_0 h / \mu_0 B_0 = 2.01452$. Using this and the free-electron g-value ($g_e = 2.0023$), the hyperfine splitting constant $A$ can be calculated in units of Gauss: $A = |\Delta B_{ex}^{(\pm)}|/\mu_B = 96.586$ G. Now, for use in Eq. (4), $G_0 = \frac{\mu_0 h}{2B_0} = 79.359.39$ G. For $E = 0$, assuming axial symmetry, one obtains from Eqs. (5) and (6): $\eta = E/D = 0$ and $F(\eta) = 1$. Finally, using these values, $D$ can be calculated, using Eq. (4), to be: $D^{(\pm)} = 65.847.15$ G. The discussion below shows that the minus sign in Eq. (4) should be chosen to fit the intensities of the two observed sextets, although the choice of sign does not affect the calculated line positions.

### 4.2. Comparison of the calculated values of the Mn$^{2+}$ line positions with the experimental values as shown in Fig. 9

The values estimated here for $g$ and $D$ have been used to simulate the Mn$^{2+}$ line positions in the 2–12 T range at 222.4 GHz. They are marked as 'CAL' in Fig. 9. It is noted that the negative sign has been used for $D$ in the simulation rather than the positive sign, to obtain the intensities of the lines consistent with the experiment. Only two allowed fine-structure EPR lines of the Mn$^{2+}$ ion occur in the 2–12 T range swept in the experimental spectrum. The calculated lines at 2.856 T and 8.549 T are very close to the centers of the corresponding experimentally observed sextets at 2.76 T and 7.888 T. These calculated values are in good agreement with these observed experimentally, given that they were only derived using the $D$ value obtained from the central hyperfine sextet in a polycrystalline spectrum. The rather large value of $D$ for the Mn$^{2+}$ ion also explains why the remaining allowed Mn$^{2+}$ lines are not observed in the 2–12 T magnetic field range, since they lie outside this range.
5. Discussion and concluding remarks

The salient features of the present EPR study on the Fe$^{2+}$ ion in a single crystal of ZnSiF$_6$·6H$_2$O are described as follows.

(i) There exist two magnetically inequivalent Fe$^{2+}$ ions. The magnetic z-axes of these ions are oriented parallel and perpendicular to the c-axis of the crystal, referred to as Fe$^{2+}$ ions at sites a and b respectively. Thus, there are six equivalent Fe$^{2+}$ ions at site b due to the crystal symmetry, which are statistically distributed equally in these orientations, as deduced from almost equal intensities of EPR lines for sites a and the ensemble of six b-sites.

(ii) The SH parameters have been estimated for the two magnetically inequivalent ions as deduced from calculated line positions. The value of the zero-field splitting parameter, $|D|$, for Fe$^{2+}$ is not very large, ranging from 600 to 2000 G for the two sites in this 0.2% doped single crystal, unlike these observed in biological systems with 100% Fe$^{3+}$ ions [1–7,18], which are at least an order of magnitude larger.

(iii) The EPR spectra are only observed below 40 K, presumably because the spin–lattice relaxation times are too short at higher temperatures, so that the EPR lines are broadened out.

(iv) The Mn$^{2+}$ ion enters the lattice of ZnSiF$_6$·6H$_2$O crystal at interstitial positions, yielding a polycrystalline spectrum.

(v) From the Mn$^{2+}$ central hyperfine sextet the values of the SH parameters g and D have been estimated as well as, the value of the hyperfine constant A. These SH parameters do produce values quite close to those observed at 222.4 GHz. The absolute sign of the ZFS parameter D for Mn$^{2+}$ has been determined to be negative.

(vi) The virtues of the single-crystal study over and above that of a powder sample are as follows. (a) Since the spectrum in the crystal is obtained for a single orientation of the magnetic field with respect to the crystal axes, the lines are much sharper, hence of greatly increased amplitude, than those in a powder sample which shows a distribution of signals obtained for a continuous range of orientations with respect to the magnetic field. In addition, the denser packing in the single crystal leads to the intensities of the lines being greater than those in a powder sample. (b) The observation that there are two magnetically inequivalent ions present was only possible in a single crystal. In a powder sample, their spectra would be indistinguishable. (c) Since the two magnetically inequivalent sites are clearly discerned, it was possible to deduce the absolute signs of the SH parameters from the relative intensities of the EPR lines for the two sites at liquid-helium temperatures. (d) The SH parameters for the two sites were unequivocally determined for the single crystal. This would not be possible in a powder spectrum.

It is hoped that the present study will stimulate further investigations into the structural and magnetic phase transitions undergone by the crystal at liquid-helium temperatures. For example, it would be of interest to study the high-field EPR spectra as a function of concentration of the Fe$^{2+}$ dopant.

Other somewhat related studies include the early X-band EPR study on 2% Fe$^{3+}$ doped ZnSiF$_6$·6H$_2$O by Rubins [19] and the FIR-magnetic resonance study on FeSiF$_6$·6H$_2$O by Champion and Sievers [20]. According to the calculations of Palumbo [21] for the 3$d$ Fe$^{2+}$ ion, with the electronic ground state $^D$ (L = 2, S = 2) in a trigonal crystal field, a cubic field splits the orbital levels into an upper doublet and a lower triplet. The trigonal field splits the triplet, so that an orbital singlet lies lowest for the case when the trigonal field ($\delta = 1200$ cm$^{-1}$) is much greater than the magnitude of the spin–orbit coupling constant ($\lambda = 104$ cm$^{-1}$). The fivefold spin multiplicity of this orbital singlet is split by the spin–orbit interaction into a ground singlet with the excited doublets at D ($M_s = \pm 1$) and 4D ($M_s = \pm 2$) above it, consistent with the second-order ZFS part of the spin Hamiltonian, given by Eq. (1). At X-band, Rubins [19] just observed the forbidden ($\Delta M_s = \pm 2$) transitions of the excited orbital doublet $M_s = \pm 1$ of the spin quintet, as shown in Fig. 7. He also points out that there is a "steady change in the crystal field parameters with increasing Fe$^{2+}$ concentration." By contrast, we have been able to observe all the allowed ($\Delta M_s = \pm 1$) transitions possible within the spin quintet ($S = 2$) at a substantially reduced Fe$^{2+}$ concentration. Thus, in our study the ZnSiF$_6$·6H$_2$O (ZFS) crystal field is likely significantly less perturbed by the Fe$^{2+}$ ions, because of the low concentration. Our observation of $|D| \leq 2$ G is substantially smaller than that observed by Rubins [19] and by Champion and Sievers [20] [in pure FeSiF$_6$·6H$_2$O (FFS)] of $\sim 10$ cm$^{-1}$ × $\sim 12.5$ kG/cm$^{-1} = 125$ G. Yi-Yang and Min-Guang [22], have given theoretical expressions for D and E for Fe$^{2+}$ sites in FFS. According to these expressions just the spin–spin interaction for Fe$^{2+}$ yields a D $\sim 6.75$ kG (using their value of $\rho = 0.18$ cm$^{-1}$). However, these calculations for FFS are made for D $> 0$, for which the spin singlet ($M_s = 0$) lies lowest, as shown in Fig. 7. In our case, for ZFS with very small concentration of Fe$^{2+}$ ions, this is not the case as D $< 0$, so that the energy-level order of the spin quintet is reversed from that for FFS (Fig. 7). In addition, these theoretical estimates of the ZFS parameters do not take into account the paramagnetic ions in the vicinity.

It is noted that the Fe$^{2+}$ ions exhibit very highly axial crystal fields with small non-axial distortion in the doped ZnSiF$_6$·6H$_2$O crystal, according to the values of the spin–Hamiltonian parameters determined here. It is likely that there occurs a Jahn–Teller distortion at Fe$^{2+}$ sites in our crystal at lower temperatures; e.g. see [23] and references therein.

Acknowledgments

S.K. Misra is grateful to NSERC (Natural Science and Engineering Research Council of Canada) for partial financial support, as well as to NHMFL for a Visiting Scientist’s award, to carry out this project in Tallahassee, Florida, J.H. Freed and D. Tipikin acknowledge financial support from NIH/NCRR Grant P41RR016292, USA. Some EPR measurements in this study were performed at the NHMFL, with the kind assistance of Dr. Andrew Ozarowski, which is funded by the NSF through the Cooperative Agreement No. DMR-0654118, the State of Florida and the DOE.
